Keywords: Gastric intramural bleeding; Epicardial fat; Pericardial effusion

A 49-year-old male patient admitted with abdominal pain and hematemesis was diagnosed with gastrointestinal bleeding. He had been taking ibuprofen 800 mg daily for a month. She had haematemesis and melena. He denied any history of abdominal pain or bleeding. On physical examination he was afebrile and diaphoretic. A complete blood count revealed a white blood cell count of 8.2 $\times 10^3/\mu\text{L}$, a hemoglobin level of 54.1% and a hematocrit of 25.8%. Platelet count was normal. He was admitted and investigated for hematemesis. He was found to have a gastric ulcer. A barium meal X-ray (TTE) showed a large pericardial effusion.

On admission, he was found to have a large pericardial effusion (Figures 1A-1C). Chest CT-enhanced computed tomography (CT) showed a large mediastinal hematoma and a clear delineation between the epicardial fat and the pericardial effusion. Epicardial fat was clearly delineated from the pericardial effusion by CT scanning (Figure 1D).

Epicardial fat may have a similar echogenicity to a pericardial effusion. While TTE is often inconclusive, CT imaging can be helpful in this case. Taking account of the clinical scenario (being a patient with abdominal pain and hematemesis), it is important to keep in mind CT imaging findings during differential diagnosis. It is also important to differentiate between a pericardial effusion and a large mediastinal hematoma. A gamma camera scan is helpful in diagnosing a pericardial effusion.
