

Overview: Epidemiology, Diagnostic and Therapeutic Challenges of Pediatric community acquired Pneumonia

Philip Britton*

Abstract

Pediatric community-acquired pneumonia (CAP) is still one of the most prevalent and dangerous illnesses in

Introduction

Children who are hospitalised for hypoxemia or respiratory distress, as well as those with probable sequelae including parapneumonic effusions, necrotizing pneumonia, or pneumothorax, should have chest radiographs. Compared to chest radiography, chest ultrasound has higher sensitivity (92 percent to 98 percent) and specificity (92 percent to 100 percent) for detecting lung consolidation. Chest ultrasound is most frequently used to assess local consequences, such as parapneumonic effusion and empyema. 9–13 Chest ultrasonographies additionally has the advantages of not using ionizing radiation and being accessible in most emergency room settings. The evaluation and interpretation of ultrasonography are heavily operator dependent, which is a significant restriction [1]. Therefore, large-scale, practical investigations are required to more thoroughly assess the efficacy of this imaging technology compared to normal chest radiography, despite these encouraging early results. Numerous pathogens, such as viruses and bacteria, can cause the diverse disease pneumonia. In the past, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes*, and *Staphylococcus aureus* were thought to be the main causes of CAP. However, the prevalence of sickness brought on by *Streptococcus pneumoniae* and *Haemophilus influenzae* has significantly decreased since routine childhood vaccination against these infections was introduced. In addition, extremely sensitive molecular tests for viral respiratory infections have increased awareness of the role that viruses play in CAP. A 2004 study by Michelow and colleagues¹⁵ is a good example of an aetiology study conducted before the PCV era [2].

Materials and Method

The pathogens in 154 hospitalised children with radiographically confirmed lower respiratory infections at a single institution were identified using conventional culture techniques, pneumolysin-based polymerase chain reaction (PCR) assays, viral direct fluorescent antibody tests, and serologic tests for viruses, *Mycoplasma* spp, and *Chlamydia* spp. *Streptococcus pneumoniae*, which was found in 73 percent of the children with bacterial sickness, was the most often found infection in the majority of patients (60 percent), whereas viruses were

found in 45 percent of the children. More than 2300 paediatric CAP hospitalizations in the US were the subject of the multicenter Centers for Disease Control and Prevention (CDC) Etiology of Pneumonia in the Community (EPIC) Study, which was carried out from 2010 to 2012. Eight distinct viruses were identified in this investigation using serology and nasopharyngeal PCR; usual bacteria were identified using culture-based techniques and whole-blood PCR (pneumococcal lgt-A); and atypical bacteria were identified using nasopharyngeal PCR [3]. In contrast to bacteria, which were only found in 15% of children, viruses were found in more than 70% of young ones. Respiratory syncytial virus (RSV), human rhinovirus, human metapneumovirus, and adenovirus were the most prevalent viral infections, all of which were found in more than 10% of children. Children under the age of 5 were more likely to contract RSV, adenovirus, and human metapneumovirus. Compared to older kids, 5 years old. *Streptococcus pneumoniae* was only found in 4% of children in the CDC EPIC survey, although bacteria were found in about 15% of kids overall, highlighting the influence PCV has had on the epidemiology of paediatric CAP. The most common bacterial pathogen discovered was *Mycoplasma pneumoniae*, which was found in 8% of children, including 19% of school-aged children but just 3% of children under the age of 5. In 1% or fewer of the kids, other germs were discovered. Importantly, in the CDC EPIC study, 19% of the children had no infection found, underlining the ongoing need for improved diagnostics and cutting-edge pathogen detection methods [4].

Epidemiology

Mycobacterium tuberculosis, fungi, *Burkholderia cepacia*, *Aspergillus fumigatus*, and *Pseudomonas aeruginosa* are other pathogens that are less frequently observed in US children. These infections typically affect people who have underlying risk factors, such as immune-compromising conditions, chronic illnesses like cystic fibrosis and spinal muscular atrophy, or a history of international travel. Patients who fail to respond to therapy for more prevalent etiologic agents should also be suspected of having these infections. Blood cultures should be taken in children hospitalised with CAP, according to the 2011 PIDS/IDSA CAP guideline. Blood cultures in this situation, however, only detect a pathogen in 2 to 7 percent of CAP patients. Blood cultures are more frequently positive in kids with parapneumonic effusion [5], with rates ranging from 10% to 35%. Blood cultures are not typically advised in the outpatient context due to the low positive rates and the likelihood that the results will alter care. Blood cultures presently offer the best chance to identify typical bacterial infections in the majority of children with CAP, despite their low yield. By only using blood cultures on patients who have a higher pre-test likelihood of having a positive culture, such as those who are very unwell or have parapneumonic pneumonia, the diagnostic yield of blood cultures can be maximised.

Patients who have received antibiotics prior to specimen collection experience much reduced pathogenic organism isolation. Additionally, studies have shown that every additional milliliter of blood collected results in a higher yield of blood cultures [6]. For unexplained reasons, obtaining sufficient weight-based blood volumes is also linked to lower contamination rates in blood cultures. Following the right sterile collection procedures will also help to reduce contamination rates. Every time pleural fluid is taken, pleural fluid cultures should be carried out because they are positive in up to 35% of cases. But other than

when required for clinical care, it is impractical to obtain pleural fluid specimens due to the intrusive techniques connected with sampling the pleural space. Except in cases of failure to respond to medication, extremely severe pneumonia, or immunocompromised hosts in whom opportunistic microorganisms are suspected, bronchoalveolar lavage is infrequently needed in CAP. Due to the inability of the majority of young children with pneumonia to produce an acceptable sputum sample, sputum cultures have a low diagnostic yield in children. Antibiotic pretreatment reduces diagnostic yield even further. The possibility of gathering sputum samples from young infants using induced sputum has been investigated, however its usefulness is constrained. In children with pneumonia, upper respiratory tract bacteria are frequently found, and pathogen recovery rates are comparable to those of children who do not have pneumonia [7].

Diagnosis

Adult patients with pneumonia are frequently evaluated with pneumococcal urine antigen testing. However, due to high rates of nasopharyngeal colonisation in children, the detection of *Streptococcus pneumoniae* urine antigen is linked to false-positive results. More recently, a serotype-specific urine antigen detection technique for people with pneumonia has been created and validated. It is yet to be seen if this test would be beneficial for children. Whole-blood pneumococcal PCR (lyt-A) has been utilised in epidemiologic research, such as EPIC and Pneumonia Etiology Research for Child Health, while not being frequently employed in clinical settings (PERCH). When compared to culture-based approaches, advantages could include increased sensitivity, quick turnaround times, and reduced impact from antibiotic pretreatment [Figure 1]. *Streptococcus pneumoniae* PCR results for 2.5 percent of the children examined in the EPIC research were positive. Only 1% of children had pneumococcus in their blood cultures, however. In the PERCH trial, only 44 children

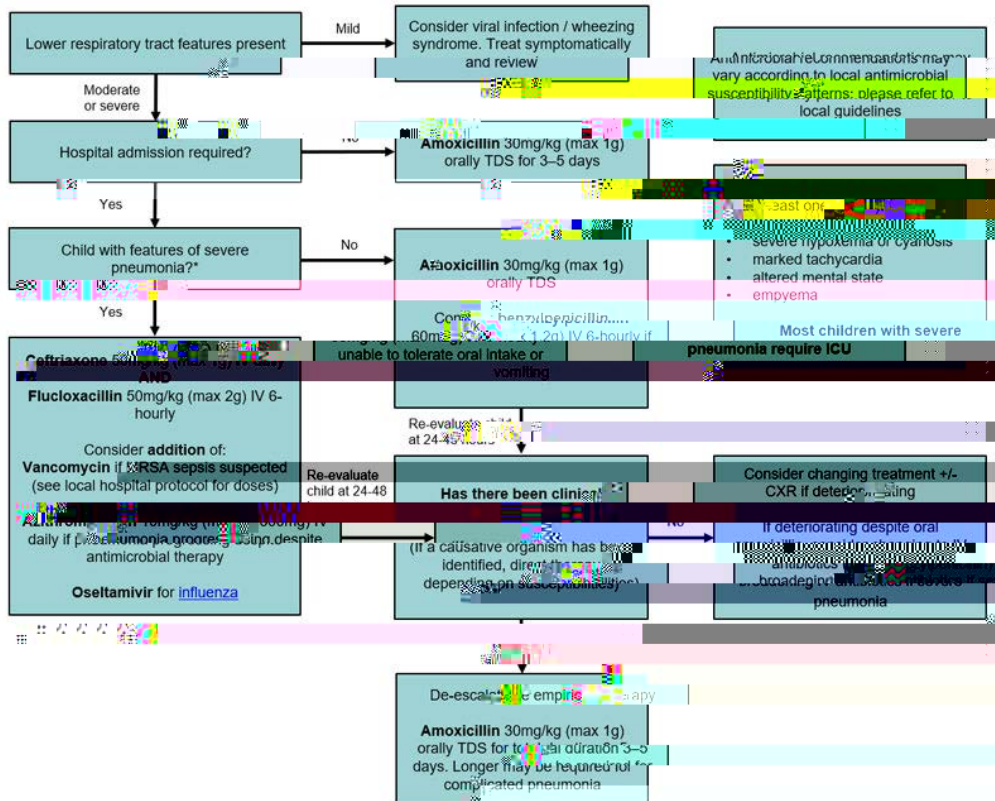

Figure 1:

(denominator not given) had a positive blood culture for *Streptococcus pneumoniae*, compared to 291 children with pneumonia who were pneumococcal PCR-positive. Furthermore, the PERCH investigation found pneumococcal DNA in the blood of 273 control children despite earlier research showing 100% specificity of *lyt-A* pneumococcal PCR from blood (5.5 percent). As a result, interpretation is hampered by subpar test specificity even though pneumococcal PCR may boost detection rates over blood cultures [8].

Discussion

Despite recent developments, CAP still has a high morbidity and fatality rate and is difficult to diagnose and treat. The introduction of molecular diagnostics has highlighted the critical role that respiratory viruses play in disease pathogenesis while also posing new challenges [9]. Vaccination against *Haemophilus influenzae* type b and *Streptococcus pneumoniae* has significantly decreased the rates of invasive disease caused by these pathogens. This new information raises the question of whether antibiotic medication would be beneficial for all CAP patients and, if so, which treatments could be most efficient. However, limitations of the available diagnostics prevent progress in answering
